Statistical Analysis of Lowlevel High Density Oligonucleotide Array Data

> smallTalk 2003 July 15, 2003 San Jose

Ben Bolstad <bolstad@stat.berkeley.edu</p>
Biostatistics
University of California, Berkeley
http://www.stat.berkeley.edu/~bolstad

### Introduction

- What is low level analysis and why do we do it?
  - Analysis and manipulation of probe intensity data
    - Expression calculation: Background, Normalization, Summarization
    - Determining presence/absence
    - Quality control diagnostics
  - Hopefully it will allow us to produce better, more biologically meaningful gene expression values
  - We want accurate (low bias) and precise (low variance) gene expression estimates

### Where do we start?

We skip image analysis.

We start with probe intensity data from CEL files. It is the probe intensity information that we will use for our low level analysis.

# Computing expression summaries: A 3 step process

Background/Signal adjustment (B) Normalization (N) Summarization (S) Let X be cel file data from multiple arrays then

### Expression values = S(N(B(X)))

## **Background/Signal Adjustment**

- A method which does some or all of the following
  - Corrects for background noise, processing effects
  - Adjusts for cross hybridization
  - Adjust estimated expression values to fall on proper scale
- Probe intensities are used in background adjustment to compute correction (unlike cDNA arrays where area surrounding spot might be used)

## **Background Signal Methods**

### Affymetrix

- Location dependent background based on grids
  - I will refer to this as the MAS 5 background
- Originally proposed subtracting MM from PM but this is problematic because as many as a third of MM's are greater than the respective PM
  - No longer used
- Now uses what they refer to as the Ideal Mismatch which is MM when possible and something else when not possible (designed so that there is now no negatives)
  - Call this IMM

### **RMA convolution model**

# Convolution model is suggested by looking at density of observed empirical distributions

### **Convolution Model**

### • O = S + N

- O is observed PM, S is signal (assumed exponential), N is noise (assumed normal, truncated at zero)
- Correction is then

$$E\left(S \mid O = o\right) = a + b \frac{\phi\left(\frac{a}{b}\right) - \phi\left(\frac{o-a}{b}\right)}{\Phi\left(\frac{a}{b}\right) - \Phi\left(\frac{o-a}{b}\right) - 1}$$

 $a = o - \mu - \sigma^2 \alpha, b = \sigma$ 

## A Standard Curve Adjustment Based on Spike-in Information

Observes that there is a curve that relates observed expression and spike-in concentration. The ideal would be to have a linear relationship between concentration and computed expression. The curve gives us a concentration dependent adjustment

### What about non-spikeins?

- We don't know a concentration for most probesets. If we did, or if we had a variable that related to concentration, the adjustment would be easy to perform
- Fit the following model

$$y_{1i}^{(k)} = \alpha_i^{(k)} + \mathcal{E}_i^{(k)}$$
$$y_{2i}^{(k)} = \alpha_i^{(k)} + \gamma^{(k)} + \mathcal{E}_i^{(k)}$$

• Where  $y_{1i}^{(k)} = \log_2 PM_i^{(k)}$  $y_{2i}^{(k)} = \log_2 MM_i^{(k)}$ 

### **Y** Relates to Concentration

Expression levels vs Gamma

# Establishing a Relationship Between $\gamma$ and Concentration

## The Two Curves Yield an Adjustment Curve

### Normalization

"Non-biological factors can contribute to the variability of data ... In order to reliably compare data from multiple probe arrays, differences of non-biological origin must be minimized."

 Normalization is a process of reducing unwanted variation across chips. It may use information from multiple chips

### **Normalization Methods**

Complete data (no reference chip, information from all arrays used) Quantile normalization (Bolstad et al 2003) Contrast (Åstrand) Cyclic Loess Baseline (normalized using reference chip) Scaling (Affymetrix) Non linear (Li-Wong) Methods already compared in Bolstad et al (2003)

### Why quantile normalization?

- Quantile normalization found to perform acceptably in reducing variance without drastic bias effects
- Quantile normalization is fast

### Summarization

- Reduce the 11-20 probe intensities on each array to a single number for gene expression
- Main Approaches
  - Single chip
    - AvDiff (Affymetrix) no longer recommended for use due to many flaws
    - Mas 5.0 (Affymetrix) use a 1 step Tukey biweight to combine the probe intensities in log scale
  - Multiple Chip
    - MBEI (Li-Wong dChip) a multiplicative model
    - RMA a robust multi-chip linear model fit on the log scale

# Parallel Behaviour for both a spike-in and a non spike-in

### **RMA Model**

 To each probeset (k), with i being number of probes and j being number of chips, fit the model:

$$y_{ii}^{(k)} = \alpha_{i}^{(k)} + \beta_{i}^{(k)} + \varepsilon_{ii}^{(k)}$$

where  $\alpha_i^{(k)}$  is a probe effect and  $\beta_j^{(k)}$  is the log gene expression.  $y_{ij}^{(k)}$  is the log2 background adjusted and normalized PM intensity

- Different ways to fit this model
  - Median polish quick
  - Robust linear model yields good quality diagnostic tools

### **Affymetrix Spike-in Data**

### • 59 chips. All but 1 of the rows are done as triplicates

### Focus will be on assessing the impact of background adjustment methods

- Impact of normalization has been previously addressed in Bolstad et al (2003)
- We will compare the impact of different background methods on expression values by
  - Signal adjusting using the chosen method
  - Normalizing using quantile normalization
  - Summarization using RMA: median polish
- Then we will compare the results

# Background Methods to be Compared

- None
- MAS 5.0 location specific background
- Ideal Mismatch
- MAS 5.0 and Ideal Mismatch
- RMA convolution model
- Using standard curve based on spike-in information to adjust signal

## **Computing Relative Expression**

- We will average in log scale across spike-in concentration replicates
- If E<sub>i,j</sub> is expression of probeset i in group j, then expression difference between group 1 and 2 is

• 
$$M_i = E_{i,1} - E_{i,2}$$

 There are 14 dilution groups so there are 14\*13/2 = 91 different comparisons for each probeset Observed expression versus spike-in concentration
